ABSTRACT
Submarine cables placed on the seabed are susceptible of suffering corrosion processes. Damages to the different parts of the cable might happen and corrosion could be a life-limiting factor. Accelerated laboratory tests have been carried out on two single cable core designs with different metallic screens: one comprised of aluminum sheet and copper wires, and the other comprised of helicoidal copper tape. The external jacket has been intentionally damaged thus exposing the metallic screen to a synthetic seawater media. Obtained results indicate that the corrosion rate of copper in seawater decreases when coupled with aluminum due to a galvanic effect.

Submarine cable, corrosion, metallic screen, accelerated tests

EXPERIMENTAL PROCEDURE: MATERIALS AND METHODS

Cable designs
Two single core cables with different metallic screens have been studied. One cable comprised of aluminum sheet and copper wires, and the other comprised of helicoidal copper tape. In the first cable design, the cross linked polyethylene (XLPE) layer between the copper wires and the aluminum tape, is not continuous, with some areas of the aluminum and copper wires in physical contact. Therefore, a risk of galvanic corrosion is not discarded if the aluminum tape (anodic or more electronegative) is shorted to the copper wires (cathodic or more electropositive).

The two cable designs are shown in Fig. 1.

Impressed anodic current tests have been carried out in damaged jacket samples. The HDPE external layer was punctured in four places leaving the copper helicoidal tape or the copper wires for the aluminum + copper design uncovered. The 4 holes, each with a diameter of 10 mm, were arranged spirally at longitudinal intervals of about 50 mm and circumferential spacing of 90º. This way of producing local damage was similar to that exposed in references [1, 2].

Corrosion degradation could also increase the electrical resistance of the metallic screen materials. One of the purposes of this screen is to provide a path for the flow of fault current. Thus measurements of the electrical resistance have been conducted on damaged samples exposed to the synthetic seawater.

Finally, leaching tests have been carried out in order to evaluate the amount of copper and aluminum that can migrate from the cable, due to the corrosion of the metal screen in contact with seawater.
